ABSTRACT

Replication Protein A (RPA) is an evolutionary conserved essential complex with single-stranded DNA binding properties that has been implicated in numerous DNA transactions. At damaged telomeres, *Saccharomyces cerevisiae* RPA recruits the Mec1-Ddc2 module of the DNA damage checkpoint network, its only known function in DNA damage signaling. Here, we describe *rfa1* mutants (*rfa1*-1, *rfa1*-9, *rfa1*-10, *rfa1*-11 and *rfa1*-12) that are proficient in this checkpoint but nevertheless exhibit deregulation of cell cycle control upon telomere uncapping induced by the *cdc13*-1 mutation. Overriding of this damage-induced checkpoint-independent cell cycle block in the *rfa1* mutants was suppressed following genetic inactivation of either *TEL1* or *EST2/telomerase*. Altogether, our results suggest that a previously non suspected function of RPA is to block cell cycle progression upon telomere uncapping using a yet unidentified pathway that functions in a Mec1-Ddc2-independent manner. We propose that in the *rfa1* mutants, ill-masking of uncapped telomeres provokes inappropriate access of Tel1 and inappropriate functioning of telomerase, which, by yet unknown mechanisms, allows cell division to take place in spite of the block established by the DNA damage checkpoint. In the present study, we also observed that upon telomere uncapping, *rfa1*-12, but not the other studied *rfa1* mutants, triggered telomeric recombination in the presence of functional telomerase. In conclusion, the present study identifies a novel pathway of telomere end protection that utilizes a previously unsuspected function of RPA at the telomeres.
1. Introduction

Early in their discovery, telomeres, the extremities of eukaryotic linear chromosomes, were regarded as a protective cap that prevented fusion between chromosomes [1,2]. Confirming these early assumptions, it is now still widely accepted that the main function of telomeres is to protect the genome against the occurrence of all events that normally promote repair of intrachromosomal DNA breaks, homologous recombination and non homologous end-joining (NHEJ), principally, including DNA damage signaling and checkpoint operation [3,4]. It is worth stressing that the second main function of telomeres, namely recruiting telomerase for telomere replication, also represents a sort of telomere end protection as it allows to regularly add telomeric DNA sequences to the eroding telomeres of dividing cells [5]. Extensive studies on telomeric proteins from various organisms, starting in the 1990s, led to the notion that the association of these telomeric proteins with telomeric DNA provides efficient means for masking these natural DNA double-strand breaks (DSBs) from inappropriate repair.

To date, in various organisms, a number of telomeric proteins have been implicated in preventing access of various DNA modification proteins to the telomeres. In the budding yeast Saccharomyces cerevisiae, Rap1, which binds telomeric double-stranded DNA repeats, inhibits both telomerase-dependent telomere elongation and telomere fusions by NHEJ [6-8]. The Rap1-Rif1-Rif2 complex in fact functionally resembles shelterin, the telomere end protection complex in mammals [9]. The Yku complex, which plays a major role in NHEJ, also localizes at the telomeres, at the junction between the double-stranded and single-stranded DNA (ssDNA) repeats where it functions in telomere end protection [10]. Finally, another major component for telomere capping in S. cerevisiae is a heterotrimeric complex composed of Cdc13, Stn1 and Ten1 that binds the single-stranded overhangs of the telomeres [11-14]. Recent work has shown that Rif2 levels are reduced at short telomeres and that this is important for the recruitment of Mre11-Rad50-Xrs2 (MRX) and of Tel1 at these telomeres [15], an event leading to the recruitment of telomerase for re-elongation [16-20]. By favoring telomerase recruitment, the reduction of Rif2 levels may therefore help distinguish short telomeres from DSBs [15]. In the same study, at short telomeres, Mec1 and Replication Protein A (RPA) levels were found to be strongly reduced compared to their levels at DSBs, thus providing a way to prevent putative DNA damage signaling and DNA repair attempts [15].

RPA is a major, evolutionary conserved, ssDNA-binding complex that is essential for numerous transactions during DNA synthesis and DNA damage signaling and repair [21-24] everywhere in the genome including, in the budding yeast S. cerevisiae, at the telomeres [25]. The unique function of RPA in DNA damage signaling identified to date, in both humans and S. cerevisiae, is to recruit the ATR/ATRIP and Mec1-Ddc2 module of the DNA damage
checkpoint machinery, respectively [26]. Under normal circumstances, in cells with undamaged telomeres, Cdc13 prevents Mec1 activation [11] and, presumably therefore, RPA recruitment. However, it is not known yet whether Cdc13 acts primarily through limiting end resection or whether it also blocks, by competition, RPA binding to the telomeric ssDNA [4,14]. In humans, the interactions between POT1 and RPA have been better documented, with the recent discovery of a TERRA- and hnRNP-based mechanism that can displace RPA, but not POT1, activity [27,28].

It is crucial to fully understand the relationships between telomere uncapping and cell cycle progression as efforts to uncover the underlying mechanisms driving genome instability in cancer cells have revealed a prominent role for telomeres [29]. Telomere uncapping is not an unusual fate as, for instance, the numerous events leading to telomerase recruitment at the telomeres may provoke transient but necessary periods of loss of telomere end protection. DNA replication itself is susceptible to create telomeric damage resulting from pausing or even stalling of the replication forks in the telomeric regions due to the repetitive nature of the DNA sequences [30-32]. In the present study, to better understand the relationships between telomere uncapping and cell cycle progression we analyzed mutants of S. cerevisiae RPA, previously described [33], in a genetic context that has been extensively used as a mean to provoke telomere uncapping, namely the temperate-sensitive cdc13-1 mutation [11].

2. Experimental procedures

2.1 Yeast strains, viability assays and Western blotting

Yeast strains used in this study were derivatives of BF264-15Daub (ade1 his2 leu2-3,112 trp1-1a ura3Dns), as described previously [12]. Yeast cultures were grown at the indicated temperatures in YEP (1% yeast extract, 2% bacto-peptone, 0.005% adenine, 0.005% uracile) supplemented with 2% glucose (YEPD), sucrose or galactose, or in selective minimal medium. All strains were made isogenic by back crossing at least five times against our genetic background. Strain origins, prior to back crossing, were as described previously [34].

Construction of the rfa1 mutants analyzed here has been described previously [33]. Activation of the checkpoint kinase Rad53 was assessed by Western blotting as described previously [33].

The viability of cells previously grown in liquid was determined by performing and analyzing the so-called “drop tests” or “spot assays”. To do this, cells from exponential growth cultures were counted with a hematocytometer and the cultures were then serially diluted by 1/5th or 1/10th and spotted onto either selective plates or YEPD non-selective plates, as required, and incubated at the desired temperature for 2-3 days before being photographed.
2.2 Telomere length measurement, telomere organization and detection of ssDNA

Assessment of telomere length and telomere organization in cells with either non-recombining or recombining telomeres was done as described previously [12]. Briefly, genomic DNAs were prepared, separated in a 0.9% agarose gel (in TBE) run in TBE buffer overnight and, after denaturation, transferred and hybridized with a 270 base pair TG$_1$-32$^P$-labeled telomeric probe as described previously [12]. Following digestion of genomic DNA with XhoI, to cut within the Y' regions of chromosomes, telomere tracts of wild-type cells appear as a broad band of ~1.1-1.4 Kb which represents the average length of most chromosomes. Telomeric recombination was assessed as previously described [37]. Detection of ssDNA at the telomeres was performed as described previously [13,34]. Results were analyzed using an FLA-5100 Fuji phosphorimager or a GE Storm phosphorimager and the ImageGauge software.

3. Results

3.1. rfa1 mutants defective in telomeric damage-induced cell cycle progression independently of the DNA damage checkpoint

Temperature-sensitive cdc13-1 mutant cells of Saccharomyces cerevisiae exhibit uncapped telomeres under the form of abnormally high levels of ssDNA in both telomeric and subtelomeric regions of the chromosomes [11]. There is both genetic and biochemical evidence that RPA is recruited at cdc13-1-induced telomeric DNA damage sites [25,26]. Yet, although RPA recruited at DSBs mediates repair by homologous recombination [35], the cdc13-1 cells do not trigger recombination or any other apparent signs of repair. In agreement with this view, cdc13-1 cells experiencing telomeric recombination due to inactivation of telomerase could now grow at the semi-permissive temperature of 29°C (Figure 1A, B). Presumably, in these cells telomeric recombination provided some sort of DNA repair, as observed in post-senescence survivors from telomerase-negative cells [36]. It has been previously established that the slow growth of cdc13-1 cells at 29°C, as well as the total arrest of proliferation at temperatures above 32°C, was due to activation of the Mec1-Rad53-Mec3 DNA damage checkpoint network, which induces a block to cell cycle progression [11]. Thus, as shown by Hartwell and colleagues [11] and subsequently by several other laboratories, telomerase-positive cdc13-1 cells in which the DNA damage checkpoint had been inactivated exhibited improved growth at 29°C (Figure 1C; override of the arrest by the rad24Δ mutation; compare rows 1 and 2; Rad24 is a component of an RFC-like complex that is essential for loading the Mec3-Ddc1-Rad17 checkpoint complex).

We previously isolated rfa1 mutants that, in a telomerase-negative background, were specifically deficient in type I telomeric recombination on the Y' subtelomeric sequences (but
not in type II recombination on the TG1-3 repeats) but proficient in activating the DNA damage checkpoint [33]. In the current study, we analyzed these rfa1 mutants (see mutations in Table 1) in a cdc13-1 background. The rfa1-1, -9, -10, -11, and -12 mutants rescued cdc13-1 at 29°C in a way similar (although to different extents) to the checkpoint-deficient mutants rfa1-t11 and rad24Δ (Figure 1C; note that rfa1-12 was not deficient in type I recombination but was used, in the previous study, as a negative control; ref. 33). rfa1-t11, first described in ref. 35, was later shown, in the cdc13-1 background, to be checkpoint-deficient [25], the mutant protein being defective in recruiting the Mec1-Ddc2 checkpoint complex [26]. Therefore the rfa1-t11 and rad24Δ mutations each impinge on one of two parallel pathways of the same checkpoint network, thereby explaining their similar phenotypes upon cdc13-1-induced damage (Figure 1C). Surprisingly, the rfa1 mutants from our previous study [33] analyzed here, although failing to arrest upon damage (Figure 1C; compare rows 1, 2 and 3-7), were still proficient in activating the DNA damage checkpoint, as judged by full activation of Rad53, a pivotal protein kinase essential for this checkpoint (Figure 2A), thus confirming our previous analysis [33]. To further document this apparent contradiction, we set out to genetically inactivate a component of the DNA damage checkpoint pathway in the cdc13-1 rfa1 double mutants. The rationale for these experiments was that simultaneously inactivating two checkpoint genes in the same DNA damage response pathway does not provoke a more severe checkpoint defect than inactivating either one of these two same genes (see, for instance, ref. 37, 38). Combining an rfa1 mutation with a mutation in a gene of the checkpoint network, here MEC3, resulted in a clear additional effect in the cdc13-1 background, an effect that was best visible at 30°C (Figure 2B).

Simple observation of the checkpoint-deficient cdc13-1 rad24Δ and cdc13-1 rfa1 mutants under the light microscope evidenced two different types of arrest existing (Figure 2C). In seminal papers that led to the discovery of a DNA damage checkpoint pathway in all eukaryotic cells, Hartwell and colleagues observed that checkpoint-negative cdc13-1 double mutants failed to arrest in the G2 phase and died rapidly after a few cell divisions following shift to the restrictive temperature [37,39,40]. After 2 h at 34°C, cdc13-1 rad24Δ mutant cells indeed exhibited the behavior previously described by these authors, while the cdc13-1 rfa1-9 mutant did not, and, instead, arrested in the G2 phase very much like the checkpoint-proficient cdc13-1 mutant (Figure 2C). This strongly suggested that the mechanisms deregulated in the rfa1 mutant are not the same as those deregulated in the classical checkpoint mutant.

It is important to note that checkpoint deficiency leading to improved growth is specific for the cdc13-1 mutation and is usually explained by the fact that, at semi-permissive temperatures for growth, the telomeric DNA damage is not too severe and can be tolerated.
through many rounds of cell divisions [11,37,41]. However, this is different in a large number of other DNA-damaging backgrounds tested, such as the temperature-sensitive cdc17-1 mutant, in which abrogation of the checkpoint results in a decrease in cell viability as temperature increases [37]; CDC17 codes for the catalytic subunit of the DNA polymerase alpha-primase complex; ref. 42,43). Interestingly, while the ddc1Δ mutation and the rfa1-t11 mutations, both abrogating the DNA-damage checkpoint, decreased cdc17-1 cell survival at the semi-permissive temperature of 32°C, the rfa1-12 mutation had no effect, further suggesting that this mutant is not deficient in DNA-damage checkpoint (Figure 2D).

In summary, by biochemical (Fig. 2A), genetic (Fig. 2B, D) and morphological (Fig. 2C) criteria, the data above established that upon cdc13-1-induced telomeric DNA damage the rfa1-1, -9, -10 and -12 mutations, although provoking a deregulation in cell cycle arrest apparently similar to that in DNA damage checkpoint mutants (Figure 1C), nevertheless did not impinge on the same targets for controlling cell cycle progression.

3.2 Rescue of cdc13-1 by rfa1-1, -9, -10, or -12 is not due to a decrease in DNA damage

The 5' to 3' double-stranded DNA EXO1 exonuclease is the main exonuclease and only one identified to date responsible for telomeric CA strand digestion [44-46], creating the long TG ssDNA overhang in cdc13-1 cells at restrictive temperature that is at least part of the damage sensed by the DNA-damage checkpoint [11]. Potentially, the rfa1 mutants analyzed here could rescue cdc13-1 growth by preventing access of Exo1 to telomeric DNA, thereby decreasing the amount of damaged telomeric DNA. As expected from previous results [44], deleting EXO1 partially rescued cdc13-1 cells at 29°C (Figure 3A, compare rows 1 and 6), to the same extent as the rfa1 mutants and the DNA-damage checkpoint mutants. We reasoned that if the Rfa1 mutant protein acted through Exo1 to rescue cdc13-1 (in other words if the rfa1 mutation led to inactivation of Exo1), then the triple cdc13-1 rfa1 exo1Δ mutant would grow like the double cdc13-1 rfa1 and the cdc13-1 exo1Δ double mutants. However, on the contrary, we observed that the triple cdc13-1 rfa1 exo1Δ mutants grew better than the two corresponding double mutants (Figure 3A, compare rows 7-10 to row 6).

These data strongly suggested that in the rescue of cdc13-1 these rfa1 mutations were not acting by preventing Exo1 access to telomeric DNA.

To confirm the data above by a distinct approach, we prepared genomic DNAs from the cdc13-1, cdc13-1 mec3Δ, cdc13-1 rfa1-t11, cdc13-1 exo1Δ and cdc13-1 rfa1 mutants and set out to detect telomeric ssDNA in these cells after growth at the restrictive temperature of 34°C by applying native conditions of hybridization to the telomeric probe. For the denatured control gel, the genomic DNA was digested with EcoRI instead of the more commonly used XhoI enzyme, because the EcoRI site is more centromere-proximal than the
**XhoI** site, releasing telomeric fragment of ~ 4.0 Kb instead of ~ 1.2 Kb for **XhoI**. Therefore, the **EcoRI** site is far enough from the telomeric ssDNA for the enzyme to cut efficiently. On the native gel, the **XhoI**-digested DNA displayed the classical smear characteristic of abnormal accumulation of telomeric ssDNA induced by the **cdc13-1** mutation [11] in all strains, except for the **cdc13-1 exo1Δ** and **cdc13-1 exo1Δ rfa1-12** strains, (Figure 3B), as expected from the genetic data of Figure 3A. Therefore, these **rfa1** mutants do not prevent telomeric degradation by Exo1 and, more generally, do not appear to lead to a diminution of **cdc13-1**-induced telomeric DNA damage.

### 3.3 The rfa1-12 mutation can trigger immediate telomeric recombination at uncapped telomeres

As explained above and illustrated in Figure 1A, B, telomeric recombination can repair the **cdc13-1**-induced telomeric damage. Inferring that the rescue of **cdc13-1** by the analyzed **rfa1** mutants could possibly be due to recombination-dependent telomere repair, we looked at the structure of telomeres in these strains by Southern blot. Telomeres of otherwise wild-type cells were normal in the **rfa1** mutants (Figure 4A, left lanes). In the **cdc13-1** background and at the permissive temperature of 24°C, telomeres tended to be shorter than those in the wild type (with the exception of **cdc13-1 rfa1-1**), but still homogenous in length (Figure 4A, right lanes). We then grew the **cdc13-1 rfa1** mutants at semi-permissive temperature (29°C) for several generations to give the telomeres time to be processed by the DNA repair activities induced by the **cdc13-1** damage. In this experiment, control mutant strains also capable of growth at semi-permissive temperature, such as **cdc13-1 mec3Δ** (checkpoint-deficient; [37], **cdc13-1 bmh1Δ** [47] and **cdc13-1 exo1Δ** [44] were included. After reaching equilibrium at 29°C, telomeres in the **cdc13-1 rfa1-1**, -9 and -10 mutants were of various length depending on the mutation, but without excessive lengthening or shortening (Figure 4B) and somewhat more heterogeneous in length than at 24°C (compare Figure 4A right lanes and Figure 4B). At 29°C, the telomeres in **cdc13-1 rfa1-1** tended to be longer than in the wild type and those in both the **cdc13-1 rfa1-9** and in **cdc13-1 rfa1-10** tended to be shorter than in the wild type, just like at 24°C (Figure 4A).

In sharp contrast with the other three mutants, the **cdc13-1 rfa1-12** mutant exhibited clear disorganization of telomere organization, much more dramatic than simple variations in length or homogeneity, which, interestingly, resembled a classical profile of type II recombination (Figure 4B; ref. 48-50). Data presented below indeed established that telomeric recombination takes place in the **cdc13-1 rfa1-12** mutant at 29°C.

### 3.4 Improved growth in cdc13-1 rfa1-12 can take place in the absence of telomeric recombination
We were intrigued by the fact that the rfa1-1, rfa1-9 and rfa1-10 mutants also exhibited improved growth at 29°C in the cdc13-1 background even though their telomeres were not recombining, as shown above in Figure 4B. We therefore next asked whether the rescue of cdc13-1 growth by rfa1-12 was indeed caused by telomeric recombination, as can be found under other circumstances (Figure 1A, B). Type II telomeric recombination depends on Rad52, a protein essential for basically all types of recombination, and the Mre11-Rad50-Xrs2 (MRX) complex [36,48,49]. A diploid bearing the desired heterozygous mutations, CDC13/cdc13-1 RFA1/rfa1-12 RAD52/rad52Δ, was induced to sporulate and the drop test-based growth assays of the strains with the desired genotype performed as soon as possible after spore selection. After 3 days of growth following spore selection, rescue of cdc13-1 by the rfa1-12 mutation at 27.5°C could be readily observed (Figure 5A, compare rows 1 and 3). Most importantly, this rescue was not inhibited by the absence of Rad52 (Figure 5A, compare rows 3 and 4). We prepared genomic DNAs from these cells at day 3 (corresponding to the time at which the drop tests of Figure 5A were completed, day 0 being the time when the spore selection process was completed) and, in parallel, let these cells grow for 2 and 4 more days at 27.5°C before preparing their genomic DNAs for telomere structure analysis by Southern blot (Figure 5B). As expected, after 3 days of growth (day 3 defined above) the cdc13-1 rfa1-12 cells did not exhibit a recombining telomeric profile (Figure 5B, day 3). It was only at day 7 that the presence of a large smear of telomeric DNA attested that recombination had started (Figure 5B, day 7, left lane). Actual recombination in the cdc13-1 rfa1-12 cells was confirmed by the disappearance of that smear when RAD52 had been deleted (Figure 5B, day 7, right lane). Therefore, at early times following strain construction the cdc13-1 rfa1-12 cells grew at 27.5°C (Figure 5A) while their telomeres had not yet started to recombine, as attested by Southern analysis (Figure 5B). In summary, cdc13-1 rad52Δ rfa1-12 cells with no sign of telomeric recombination or cdc13-1 RAD52+ rfa1-12 cells prior to initiation of telomeric recombination, at day 3, nevertheless exhibited deregulated growth upon telomere uncapping, leaving us with the possibility for other mechanism being deregulated in the rfa1 mutant.

3.5 Improved growth in cdc13-1 rfa1 requires Tel1 kinase activity as well as Est2/telomerase

Following thorough analyses of genetic interactions, in a cdc13-1 background, between the rfa1 mutations studied here and mutations in genes previously implicated in telomeric pathways, we observed that, at semi-permissive temperatures for growth for cdc13-1, inactivation of TEL1 partially suppressed cdc13-1 rescue by rfa1-1 and totally suppressed that by rfa1-12 (Figure 6A). To know whether the suppression of cdc13-1 rfa1 rescue by Tel1 required its kinase activity, we modified the wild-type TEL1 chromosomal locus for expression of a tel1-kd mutation [51]. Inhibition of Tel1 kinase activity inhibited the rescue of
cdc13-1 by all rfa1 mutants to various extents, the effect being stronger for rfa1-12 (Figure 6B, top panels). The absence of a synthetic defect between the tel1-kd and rfa1 mutants in an otherwise wild-type background suggested that the genetic interactions observed between the rfa1 and tel1 mutations are linked to telomere protection and not to some other more general effect (Figure 6B, bottom panel).

Because Tel1 has been shown to mediate telomere elongation by telomerase at short telomeres, a reaction that appears to involve the initial recruitment of MRX at these ends followed by transient association with Tel1 [17-19], we performed experiments using the est2-DF338 mutation, which displays short telomeres, decreased telomerase activity and decreased binding to TLC1 [52]. The est2-DF338 mutation exhibited only slight synthetic growth defects in combination with cdc13-1 (Figure 6D, bottom left panel, compare rows 2 and 3, at 24°C). The short telomere phenotype conferred by the est2-DF338 mutation in different backgrounds is shown in Figure 6C. When combined with the cdc13-1 rfa1 mutations, the est2-DF338 mutation suppressed the rescue of cdc13-1 by the rfa1 mutations (Figure 6D).

We tested the effects of the mre11 and yku70 null mutations on the growth characteristics of the cdc13-1 rfa1 mutants. However, since both mre11Δ and yku70Δ exacerbated the growth defects conferred by cdc13-1, as previously reported by several other laboratories, this rendered the interpretation of the drop test-based growth assays of the strains difficult (data not shown).

3.6 Telomere elongation in telomerase-negative cells does not confer cdc13-1 rfa1-12 improved growth

One possible interpretation of the data above was that telomerase-mediated telomere elongation might be responsible for the deregulated growth of these rfa1 mutants upon telomere uncapping. To further challenge this hypothesis, we reasoned that it would be interesting to find a way to achieve the same goal as that resulting from telomerase functioning, namely synthesizing telomere repeats, but in the absence of telomerase. In budding yeast, an alternative pathway for adding TG1-3 repeats at the ends of telomeres is through the so-called type II pathway of telomeric recombination that takes place in telomerase-negative post-senescence survivors [36,49]. Type I survivors can also be generated in these mutants but they amplify the sub-telomeric repeats rather than the TG1-3 repeats [49]. In fact, the cdc13-1 background induces 100% type II [53]. We constructed several cdc13-1 tlc1Δ rfa1 strains as well as the cdc13-1 tlc1Δ RFA1+ as a control (TLC1 encodes the telomerase RNA subunit) and let them grow for over 100 generations, past the time required for the cells to enter telomeric senescence, around 75 generations. As expected, telomeric recombination bypassed senescence in a minority of cells and post-
senescence survivors were generated [36,54], of type II in the present situation. As shown in Figure 7, both the cdc13-1 tlc1Δ rfa1 and cdc13-1 tlc1Δ RFA1+ cells could grow at 29°C. This was expected as telomeric recombination rescues the cdc13-1 mutation as shown in Figure 1A. However, interestingly, the rfa1 mutant cells did not grow better than the RFA1+ cells, indicating that in the absence of telomerase the rfa1 mutations no longer confer growth advantage (Figure 7). To make sure that some aspect of telomerase activation was not taking place in the absence of TLC1 via the Est2 catalytic subunit, we also performed the analysis by simultaneously introducing the est2-DF338 mutation and obtained the same result ((Figure 7)). Therefore, the rfa1 mutations no longer confer cdc13-1 cells a growth advantage in the absence of functional telomerase.

4. Discussion

The present work reveals two novel important functions for S. cerevisiae RPA, one in protection against inappropriate telomere recombination, the second one in preventing, upon telomere uncapping, cell proliferation by a checkpoint-independent pathway.

S. cerevisiae RPA has been shown to assume a function in telomere length control and telomerase recruitment [55-57]. However, to our knowledge, RPA has never been shown before to play a role in preventing telomeric recombination. The interpretation of our data (Fig. 4) attesting to a role of RPA in telomere end protection is straightforward. Indeed, as shown previously for other telomere end protection proteins, notably Cdc13 and the Yku complex [14], in the presence of telomere damage, the Rfa1-12 (L227S) protein triggered type II recombination. Note that the nature of telomere uncapping provoked here, namely the temperature-sensitive cdc13-1 mutation, has been previously shown to produce 100% type II recombination [53]. Therefore, it is not known yet whether RPA also protects subtelomeric sequences from undergoing inappropriate recombination. In general, in budding yeast, two situations have been reported to be associated with the triggering of telomeric recombination and the preceding announcing events, namely telomeric senescence. The more frequent one is the combination of mutations in two telomere end protection proteins, such as cdc13-1 and yku70Δ for instance [58]. It is not currently known whether the rfa1-12 mutation by itself creates telomeric damage. The second situation that was found to associate with telomere recombination was when loss of telomere capping, again provoked by the cdc13-1 mutation, was accompanied by inactivation of the G2/M DNA damage checkpoint [34]. Although the rfa1-12 mutation does not confer a defect in that checkpoint, its implication in a parallel pathway of cell cycle control, as documented in the present study, makes the scenario observed with cdc13-1 mec3Δ mutants, for instance [34] also likely to happen with cdc13-1 rfa1-12.
In view of the present data, RPA appears to represent a previously unsuspected key factor capable of operating a switch between telomerase-based telomere maintenance and recombination-based telomere maintenance, also known as the ALT pathway. Recent data obtained in mice have suggested that the system of telomere maintenance present at a given time, telomerase or ALT, might represent an unstable equilibrium that can easily shift from one system to the other when certain proteins, for instance the RTEL1 helicase, the DNA damage checkpoints or telomerase itself have been compromised [59,60]. At present, there is no evidence that RPA can play major roles in tumor initiation or progression as a result from telomeric disturbances. In fact, to our knowledge, mutations in RPA have not been directly associated with cancer, with the exception of a report that mice engineered to heterozygously express RPA1 L221P displayed elevated rates of cancer [61]. This was probably due to the L221P mutation conferring defects in checkpoints and homologous recombination, as seen in yeast with the equivalent mutation [62].

The present data represent further analysis of previously described rfa1 mutants, rfa1-1, rfa1-9, rfa1-10, rfa1-11 and rfa1-12 [33]. Importantly for the comprehension of the present work, these mutations were shown to be resistant to methylmethane sulfonate treatment, like the wild type but unlike ddc1Δ and rad51Δ, and were therefore presumed to be proficient in DNA repair [33]. Here, these mutants have been shown to confer deregulation of the cell cycle arrest that is normally triggered upon telomere uncapping, provoked by the temperature-sensitive cdc13-1 mutation. This should not have been surprising, since a similar phenotype had already been reported concerning the rfa1-t11 mutant ([25]; see also Fig. 1C). Suppression of cdc13-1 arrest by the rfa1-t11 mutation has been shown to be due to an inability for the Rfa1-t11 protein to recruit the Mec1-Ddc2 checkpoint complex [26]. However, suppression of cdc13-1 arrest by the rfa1 mutations analyzed here was nevertheless surprising since these mutants were previously reported to be checkpoint proficient, in this same genetic background [33], as we confirmed here (Fig. 2A). By genetics, we further demonstrated here that these Rfa1 mutant proteins acted in a separate pathway than that controlled by the Mec1-Rad53-Mec3 DNA damage checkpoint (Fig. 2B). In fact, this was obvious when examining the morphology of the mutant cells of the RPA pathway and comparing with that of the mutant cells of the checkpoint pathway (Fig. 2C). Assessment of telomeric damage strongly suggested that these cdc13-1 rfa1 mutants did not accumulate less damage than the cdc13-1 RFA1* mutant, which could have explained their improved growth, and did not impinge on the Exo1 pathway of damage generation (Fig. 3).

Initially, to try to explain the checkpoint-independent override of the cell cycle progression in the cdc13-1 rfa1 mutants, we reasoned that cell cycle control proteins should be suspected of being involved. In S. cerevisiae, besides with Mec1-Ddc2, RPA has never
been implicated in physical or functional interactions with proteins of control of the cell cycle, with the notable exception of the report of a physical interaction between Rfa1 and Cdc20 by affinity capture mass spectrometry in a high-throughput study [63]. We have investigated that possibility but have been so far unable to confirm this interaction by two hybrid or to recapitulate it by in vivo co-immunoprecipitation between chromosomally expressed Myc2–Cdc20 and HA2–Rfa1 (Grandin and Charbonneau, unpublished results).

In parallel, a thorough genetic analysis using combinations of the rfa1 mutations analyzed here and mutations in proteins involved in telomeric pathways led us to the surprising conclusion that deregulation of the cell cycle arrest in the cdc13-1 rfa1 mutants could be strongly suppressed by inactivating either TEL1 or EST2 (Fig. 6). Mre11 and Tel1 cooperate in the recruitment of telomerase at short telomeres [17-20]. It is therefore reasonable to conclude that either a lack of telomerase loading (directly through the est2-DF338 mutation or indirectly through the tel1 mutation) or shorter than normal telomeres could lead to suppression of checkpoint-independent cell cycle control deregulation in cdc13-1 rfa1. Unfortunately, we have been unable to rigorously test the effects of mutations in the MRX and Yku complexes due to synthetic growth defects with cdc13-1. Additional experiments in telomerase-negative post-senescence survivors (Fig. 7) indicated that the requirement of the rfa1 phenotype (deregulation of cell cycle control upon damage) for telomeric repeats addition by telomerase could not be mimicked by addition of these repeats by telomere recombination. We propose that wild-type RPA normally prevents cell cycle progression upon telomere uncapping by two parallel pathways. One is the already described pathway of recruitment of an essential module of the DNA damage checkpoint machinery, Mec1-Ddc2 [26]. The second one might be to block telomerase action in order to prevent further addition of telomeric repeats. Addition of telomeric repeats can provide healing, for instance at DSBs, a reaction that is normally prevented by specific proteins, such as Pif1 [64]. However, in the present situation, potential healing by telomere repeat addition would not prevent telomere uncapping in the long term, the damage being persistent due to the continuous application of the cdc13-1-mediated insult. In fact, we have seen that the telomeric damage is not less in the rfa1 mutants, at least at 34°C (Fig. 3B). However, it is possible that unscheduled functioning of telomerase at intervals simultaneously at one or more uncapped telomeres could give the cells a sort of short respite from ongoing damage, respite that would be immediately followed by insult, thus undetectable at least with the sensitivity allowed by our measurements. In the cdc13-1 rfa1 mutants, such short bursts of telomeric repeats addition might confer regular periods of relief allowing in the end improved cell proliferation compared with the RFA1+ counterpart.

Particularly noteworthy are the F238 and F269 mutations found in rfa1-11 and rfa1-10, respectively, that are conserved aromatic residues that make direct contact with ssDNA
These mutations may alter the ssDNA binding properties and affinity of RPA, its most important and fundamental attribute, and influence the telomeric pathways in which RPA is involved. In damaged cells, ill-positioned mutant RPA might give inappropriate access to Tel1. By blocking access of Tel1 at uncapped telomeres, wild type RPA might assume a function of marking the telomere for repair rather than for elongation by telomerase. Alternatively, RPA might directly bind telomerase to prevent it from being active in the presence of telomeric damage. This hypothesis is particularly interesting given the recently described physical interaction between RPA and telomerase in budding yeast [57]. We have been unable to test this hypothesis as we could not detect physical interaction between chromosomally expressed Myc18-Est2 and HA2-Rfa1 or HA2-Rfa1-12 (Grandin and Charbonneau, unpublished results). Because we clearly detect each of these proteins upon immunoprecipitation but not attached to each other neither at normal or uncapped telomeres (Grandin and Charbonneau, unpublished results), we believe that a putative RPA-telomerase physical interaction is not key in underlining the deregulation of the rfa1 mutants described here.

At the telomeres, RPA is physically present next to other ssDNA-binding proteins, such as Cdc13 and POT1, and assumes important roles in order to allow the coordinated completion of both telomere replication and telomere end protection [28]. The present data on the role of RPA in telomere end protection in S. cerevisiae will hopefully contribute to the elucidation of these pathways.

**Legends of figures**

**Figure 1.** Mutants of *RFA1* deregulated in telomere uncapping-induced cell cycle arrest. (A, B) Telomeric recombination, induced here by inactivating *TLC1*, coding for the RNA subunit of telomerase, partially rescued the temperature sensitivity of the *cdc13-1* mutation (A), an event accompanied by telomeric recombination assessed by Southern blot (B). The smear at 1.3-1.4 Kb represents the average length of the telomeres. The pattern of recombination is typical of type II recombination, amplifying the TG₁₃ telomeric repeats [49]. Note that in the *cdc13-1* background, type II is the only pathway permitted [53]. (C) Deregulation of cell cycle control upon *cdc13-1*-induced telomere uncapping was compared in checkpoint-deficient mutants, *rad24* deletion and *rfa1-t11*, and other *rfa1* mutants. All *rfa1* mutants were under the control of natural promoter in a low-copy plasmid (centromeric, of the YCplac series, expressed at one or two copies per cell; ref. 66,67) in an *rfa1* deletion background (*RFA1* is an essential gene). Last row corresponds to the *rfa1* deletion strain transformed with wild-type *RFA1* as a control. Shown schematically is the fate of *cdc13-1* mutant cells with or without an intact checkpoint at the indicated temperatures.

**Figure 2.** The DNA damage checkpoint is intact in telomere-uncapped *cdc13-1* *rfa1* mutant cells. (A) Activation of the checkpoint kinase Rad53 upon *cdc13-1*-induced telomere uncapping (2 h, 34°C) was assessed by visualizing electrophoretic mobility shifts of the protein [68]. Strains expressed *RAD53-HA₂* from the *RAD53* genomic locus under the control of native promoter and the protein was detected following immunoprecipitation and Western blotting using monoclonal anti-HA antibody. The *cdc13-1 mec1 sml1* deletion, *cdc13-1 mec3-2* and *cdc13-1 rad9* deletion mutants served as controls, Mec1, Mec3 and Rad9 being essential for Rad53 activation. All *cdc13-1* *rfa1* mutants behaved like checkpoint-proficient *cdc13-1* cells and *cdc13-1* cells harboring wild-type *RFA1*, thus indicating an absence of Rad53-mediated checkpoint defect in these mutants. *cdc13-1* *rfa1-t11* mutant cells were partially defective in activating Rad53, as described previously [25]. (B) In cell viability assays, deregulation in damage-induced cell cycle control provoked by the *rfa1* mutations (improved growth at 29°C compared with *cdc13-1* alone) was found to be additive with the deregulation provoked by checkpoint inactivation in the *mec3* deletion background, as combination of *mec3* and *rfa1* mutations (*cdc13-1 mec3 rfa1* triple mutants) rendered this deregulation more severe than in either class of the double mutants, an effect best seen at 30°C. (C) At the restrictive temperature for growth for *cdc13-1* of 34°C, the arrest of checkpoint-deficient cells, here *cdc13-1 rad24Δ*, differed from that in *cdc13-1 rfa1-9*, thus suggesting that the reasons for improved growth at 29°C (see Figure 1) were not the same for the two strains. *cdc13-1 rad24Δ* cells exhibited a typical override of the DNA damage-induced block to cell cycle progression, indicated by re-budding, while the *cdc13-1 rfa1-9*
cells continued to enlarge in size without re-budding. (D) The growth defects of the temperature-sensitive *cdc17*-1 mutant (*Cdc17* is a subunit of DNA polymerase alpha-primase) were exacerbated by the checkpoint-deficient *ddc1Δ* and *rfa1-t11* mutations, but not by the *rfa1-12* mutation, thus suggesting that the latter mutation unlike the former two ones does not confer defect in sensing the damage at the replication forks provoked by *cdc17*-1.

**Figure 3.** The *rfa1* mutations do not rescue *cdc13*-1 by diminishing Exo1-induced telomeric DNA degradation from double- to single-stranded. (A) Cell viability assays (spot tests) of *cdc13*-1 mutant strains of the indicated relevant genotypes at the indicated temperatures. The triple *cdc13*-1 *rfa1* exo1Δ mutant grew better than the double *cdc13*-1 *rfa1* and the *cdc13*-1 exo1Δ double mutants, an effect best visible at 30°C, suggesting that the rescue of *cdc13*-1 by the *rfa1* mutations did not depend on Exo1. (B) Detection of abnormally high levels of telomeric ssDNA in the *cdc13*-1 strains of the indicated relevant genotypes, following growth at 34°C for 2 h, was performed by Southern blot analysis under native conditions (right panel). Only strains harboring the *exo1Δ* mutation exhibited a clear diminution of telomeric damage, thus indicating that the *rfa1* mutations do not rescue *cdc13*-1 through a failure to activate Exo1.

**Figure 4.** The *rfa1-12* mutation triggers telomeric recombination in *cdc13*-1 cells with uncapped telomeres. (A) Cells expressing the indicated *rfa1* mutations either in an otherwise wild-type background (left) or in the *cdc13*-1 background (right) were grown at 24°C and telomere organization assessed by Southern blotting with a telomeric probe. A wild-type *RFA1*+ strain is illustrated as a control (wt). Following digestion of genomic DNAs with *Xho*I, the smear migrating at 1.1-1.4 Kb represents the average length of most telomeres, those containing Y′ subtelomeric regions. From non Y′-chromosomes, *Xho*I cutting typically generates fragments migrating at ~2.1, 2.3, 3.2 and 3.9 Kb in Southerns. (B) The *cdc13*-1 *rfa1-12* mutant exhibited telomere recombination following growth at 29°C on solid medium, here after 5 passages, one passage corresponding to restreaking of single colonies every 3 days (~30 cell divisions per passage at 29°C). Meanwhile, increasing telomere uncapping by growing the other *cdc13*-1 *rfa1* strains at 29°C (compared with growth at 24°C in panel A) led to substantial changes in telomere length and organization, different from one *rfa1* mutant to the next, but, unlike with the *cdc13*-1 *rfa1-12* mutant, not to telomeric recombination. Telomere organization in the *cdc13*-1 *mec3Δ*, *cdc13*-1 *bmh1Δ* and *cdc13*-1 *exo1Δ* strains, all exhibiting deregulated growth at 29°C (see main text), is shown for comparison.
**Figure 5.** Improved growth in cdc13-1 rfa1-12 can take place in the absence of Rad52-dependent telomeric recombination. (A) cdc13-1 rfa1-12 cells exhibited deregulated growth at 29°C even the absence of telomere recombination due to RAD52 deletion. (B) Kinetics for reaching telomere recombination upon telomere uncapping, at 27.5°C, in the cdc13-1 rfa1-12 mutant cells. Sister cells deleted for RAD52 were grown and analyzed in parallel. See main text for more detail on the experimental set-up.

**Figure 6.** Tel1 kinase activity and EST2/telomerase are required for the deregulated growth conferred by the rfa1 mutations upon telomere uncapping by cdc13-1. (A) Deletion of TEL1 suppressed improved growth of the cdc13-1 rfa1-12 mutant and partially suppressed that of cdc13-1 rfa1-1. (B) **Top panels:** Expression of a kinase dead allele of tel1 (tel1-kd) from TEL1 genomic locus also suppressed improved growth of the cdc13-1 rfa1 mutants to various extents depending on the rfa1 mutation. **Bottom panel:** In the absence of incurred damage, the simultaneous presence of one of the analyzed rfa1 mutations and of the tel1-kd mutation did not interfere with cell growth. (C) Telomere length was measured by Southern blot (P^{32}-TG_{1-3} probe, genomic DNA digested with Xhol) in strains with the indicated relevant genotypes. The est2-DF338 mutation conferred roughly equal telomere shortening in all rfa1 mutant strains, as well as in the wild type (left panel). **Right panel** shows telomere shortening in tel1 and rad50 null strains for comparison. (D) The est2-DF338 mutation suppressed deregulated improved growth conferred by the rfa1 mutations in cdc13-1 mutants with uncapped telomeres, at 27.5 or 29°C.

**Figure 7.** Growth advantage conferred by the rfa1-1, rfa1-9, rfa1-10, rfa1-1 and rfa1-12 mutations is not additive with that conferred by telomeric recombination. Telomeric recombination (as shown in Figure 1B) in post-senescence type II survivors, generated following genetic inactivation of telomerase (tlc1 disruption alone or in conjunction with the est2-DF338 mutation), led to improved growth at 27.5-29°C as expected (see Figure 1A, B). However, under these conditions the rfa1-1 mutants no longer grew better than the sister RFA1+ cells.
